## ACKNOWLEDGEMENTS

This study was made possible by the availability of reliable index data. We are grateful to all those responsible for creating and maintaining the Lehman Brothers Fixed Income Indices. We thank our colleagues in Fixed Income Research—Jeff Biby, Lev Dynkin, Dick Kazarian, Prafulla Nabar, Andy Sparks and Prashant Vankudre—for their various suggestions and patience in reading many drafts of this paper.

Publications: L. Pindyck, A. DiTizio, C. Triggiani, B. Davenport, W. Lee, D. Kramer, S. Bryant

## SECTION I: INTRODUCTION

The mortgage sector continues to present many challenges to active fixed income portfolio managers. Mortgage prepayment models and option-based valuation tools have been widely used by portfolio managers for over a decade. Yet many important questions remain unanswered. Is Option-Adjusted Spread (OAS) a reliable measure of expected excess return? How do mortgages interact with the other fixed income markets? What do these linkages imply about the key drivers of mortgage excess returns? And, finally, how should mortgages be deployed in an actively managed fixed income portfolio; in particular, when should mortgages be overweighted, and how should they be hedged? This paper addresses these questions by analyzing the performance of mortgages over the last eleven years.

In Section II, we review the historical excess returns of mortgages and other investment-grade spread sectors over the 1989-1999 period. The Lehman Brothers Mortgage Index had an average annual excess return of 28 bp over this period, significantly lower than the average index OAS of 77 bp. We attribute the discrepancy to steady improvement in refinancing efficiency over the past decade, which has caused prepayment models to consistently understate mortgage callability. This model bias has resulted in lower measured excess returns due to 1) underestimating the impact of refinancing on both prices and paydowns, and 2) assigning too large a duration to mortgages during a period of generally declining rates.

Section III examines the correlation between mortgages and other fixed income securities to assess mortgages in a portfolio context. Mortgage excess returns exhibit strong positive correlation with investment-grade corporate excess returns. The mortgage-corporate correlation is highest when prepayment risk is low or when liquidity events dominate the market. Mortgages also have linkages to Treasuries beyond the traditional measures of duration and convexity. We show that when aggregate prepayment risk is high, as indicated by a high average price of the MBS index, mortgage spreads tend to widen in Treasury rallies and tighten in backups. Due to this conditional directionality, investors should hedge mortgages at approximately 80% of their model-implied durations when the index price is above \$102.

In Section IV, we propose a five-factor empirical model to explain the historical variation in mortgage excess returns. Three of the five risk factors—convexity, vega, and prepayments—are familiar to investors. The other two risk factors—credit spread changes and spread directionality—follow from the analysis in Section III. The five-factor model explains 40%-59% of the variation in mortgage excess returns. The most important risk factors are volatility, both realized and implied, and movements in credit spreads. Risk sensitivities estimated empirically correspond closely with those implied by our valuation model.

---

Finally, in Section V, we conclude with implications for relative value and hedging. First, investors should include the impact of further reduction in origination and refinancing costs in their expectations of excess returns. Preliminary analysis suggests that using a forward-looking prepayment model would lower the current OAS for 30-year par coupon pass-throughs by 7 bp and for premium coupons by as much as 16 bp. Second, investors should consider the effects of a forward-looking prepayment model and spread directionality in determining appropriate hedge ratios. The combined impact could be quite substantial: using a forward-looking prepayment model would currently lower par coupon duration by 0.2 to 0.3 years, while spread directionality would reduce duration by an additional 0.6 years if the index price is above \$102.

---

## SECTION II: MORTGAGE PERFORMANCE SINCE 1989

In this section, we analyze mortgage excess returns from January 1989 to December 1999 to provide some historical perspective. Our analysis demonstrates the following:

1. Mortgage excess returns were lower than agency debenture excess returns, implying that investors were not compensated for taking prepayment risk over this period.
2. The average 28 bp/year excess return for the mortgage index was significantly lower than the average 77 bp OAS of the index. The observed shortfall was greater for higher dollar-price securities in the index.
3. We attribute this 49 bp discrepancy largely to the steady improvement in refinancing efficiency over the past decade, which has caused prepayment models to consistently understate mortgage callability. For 30-Year mortgages, this model bias has resulted in lower measured excess returns due to 1) underestimating the impact of refinancing on both prices and paydowns (32 bp), and 2) assigning too large a duration to mortgages during a secular decline in interest rates (15 bp).

### MORTGAGES HAVE FALLEN SHORT OF EXPECTATIONS

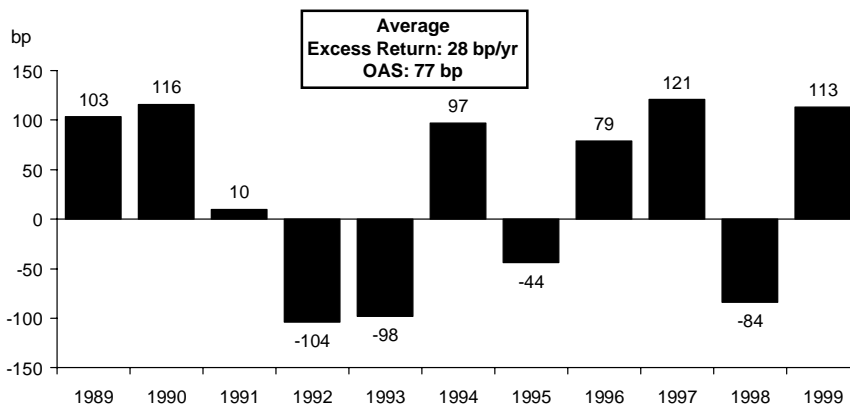

Mortgage performance has been lackluster over the January 1989 to December 1999 study period (Figure 1). The Lehman Brothers Mortgage Index had an average excess return of 28 bp per year over the past eleven years,<sup>1</sup> while the average index

---

<sup>1</sup>Our analysis focuses on excess returns of securities in the Lehman Brothers Aggregate Index. We define excess return as the security's total return minus the total return of a duration-matched portfolio of treasuries. The replicating duration-matched treasury portfolio is rebalanced every month. The excess return of an index is the market-weighted average excess return of all securities in the index.

---

Figure 1. **Excess Returns of the Lehman Brothers Mortgage Index, 1989–1999**

---

OAS was 77 bp over the same period. Since OAS is a measure of expected annual excess return, it appears that realized excess returns of mortgages fell 49 bp/year short of their target.

The underperformance of mortgages was consistent across price sectors and maturities. To illustrate, we subdivide the 30-year and 15-year mortgage indices into four price buckets: **discount** (price  $\leq$  \$98), **current** ( $98 < \text{price} \leq 100$ ), **cusp** ( $100 < \text{price} \leq 102$ ) and **premium** (price  $> 102$ ).<sup>2</sup> Historical average performance for these sub-indices is shown in Figure 2.<sup>3</sup> In the 30-year sector, excess returns are distinctly declining in dollar price despite the higher OAS of higher-priced mortgages. For example, discounts outperformed premiums by an average 48 bp per year over the 1989-1999 period, even though discount OAS was an average 10 bp lower than premium OAS over this period. In the 15-year sector, current coupon mortgages have historically posted the highest excess returns. Comparing across maturities, the 15-year mortgage sector has offered a better risk-return tradeoff than the 30-year sector in non-discount price buckets, with 1-8 bp higher average excess returns and lower risk.

We also report the performance of corporates, agencies and Asset Backed Securities (ABS) in Figure 2 for comparison. Corporate index returns were also lower than their average OAS over the study period. We attribute the discrepancy to 1) the spread widening over 1998-1999; 2) the impact of defaults, estimated at 5 bp/year; and 3) the mark-to-market impact of both downgrades and upgrades, estimated at roughly 35 bp/year. Agencies, on the other hand, produced excess returns roughly commensurate with their OAS. This is not surprising, since agencies can be modeled much more accurately than corporates or mortgages, due to their minimal credit risk and relatively straightforward optionality.

In cross-sector comparisons, mortgages had mixed performance versus similar-duration corporates and poor performance versus agencies. Versus corporates, discount mortgages outperformed long and intermediate corporates, while current coupon mortgages outperformed intermediate corporates. Cusp coupon and premium mortgages, however, generally underperformed intermediate and short corporates. Versus agencies, the average mortgage excess returns closely matched agency excess returns, despite the much higher OAS for mortgages. However, the riskiness of mortgages, as measured by the standard deviation of excess returns, was much higher than that of agencies. This suggests that mortgage investors were not compensated for bearing prepayment risk over the past eleven years.

---

<sup>2</sup> These price bucket definitions are used throughout the rest of the paper.

<sup>3</sup> We report performance statistics for the entire 1989-1999 period and for the 1989-1997 subperiod to isolate the impact of the 1998 credit/liquidity crisis.

## WHY HAVE MORTGAGES UNDERPERFORMED?

The past underperformance of mortgages relative to their OAS is attributable largely to changing prepayment expectations. Prevailing prepayment models, calibrated to past prepayment data, did not anticipate the steady improvements in refinancing efficiency realized over the past 15 years. As a result, these models understated callability during the three major refinancing waves of 1986, 1993, and 1998. An examination of peak refinancing rates during past refinancing episodes illustrates the dramatic impact of technological innovation on refinancing behavior (Figure 3). Over the 1986 to 1993 period, the refinancing threshold declined by 35 bp, while the slope of the refinancing curve increased by 30%.<sup>4</sup> Similarly, between

<sup>4</sup> Refinancing threshold is the incentive required for refinancing to become economically attractive to some homeowners, which occurs at the "elbow" of the refinancing curve. Slope is the part of the curve to the right of the elbow.

Figure 3. **Increases in Mortgage Callability: Estimated Refinancing Functions for 30-Year Unseasoned Conventional Mortgages**

1993 and 1998, the refinancing threshold declined by another 20 bp, while the slope stayed largely unchanged.

The increase in prepayment efficiency has negatively affected mortgage excess returns, both directly and indirectly. The direct effect, or the *price/paydown effect*, is obvious: faster-than-expected prepayments have resulted in price declines and negative paydown returns. However, the indirect effect, which we call *duration bias*, is subtler. Mortgage investors immediately update their prepayment assumptions with the arrival of new information; this information is aggregated in an unobservable market prepayment model. Meanwhile, changes to proprietary models, such as the Lehman Brothers Prepayment Model, occur less frequently and, therefore, with a lag. Since mortgage callability steadily increased over the study period, the market prepayment model was often more callable than proprietary models. As a result, model estimates of mortgage durations were generally longer than their true values, causing estimated excess returns to be overstated in rate backups and understated in rallies. Since interest rates declined over the study period,<sup>5</sup> the duration bias has had a net negative effect on excess returns.

### MEASURING THE IMPACT OF INCREASING MORTGAGE CALLABILITY

We examine the hypothetical effect of increasing callability on excess returns using a simulation approach. First, we estimate the price impact and duration bias using the following procedure:

<sup>5</sup> The 10-year Treasury yield, for instance, declined from 9.22% on January 3, 1989 to 6.44% on December 29, 1999.

1. We simulate the 1986 prepayment model by adjusting the current prepayment model to reflect the prevailing refinancing environment in 1986. The simulated “1986 prepayment model” combines the yield curve and volatility structure of December 29, 1999, with the refinancing sensitivity of 1986.
2. Using the “1986 prepayment model” and the yield curve of December 29, 1999, we determine the coupons and durations corresponding to mortgages with dollar prices of \$96, \$99, \$101, and \$104. These hypothetical securities represent the discount, current, cusp, and premium sectors of the mortgage market in 1986. All calculations are done at an OAS of 55 bp.
3. We recalibrate the prepayment model to mimic the refinancing sensitivity in 1993. The “1993 prepayment model” is used to re-estimate the dollar price and duration of the four hypothetical mortgage securities. We attribute the change in dollar price and duration to the increase in refinancing efficiency over the 1986 to 1993 period.
4. The procedure is repeated to determine the effect of improvement in refinancing technology between 1993 and 1998.

The results of this analysis are shown in Figure 4, which highlights the significant price impact of the changing callability on cusp and premium collateral. The price of the hypothetical premium coupon dropped from \$104-00 to \$103-02 due to the refinancing efficiency achieved between 1986 and 1993. This sector lost a smaller, but still significant 13/32nds from 1993 to 1998. Figure 4 also highlights the duration bias, the difference in duration between a forward-looking model and a model benchmarked to the previous refinancing wave. The duration bias is also

Figure 4. **Price Impact and Duration Bias of Enhanced Refinancing Efficiency, 1986 versus 1993 and 1993 versus 1998\***

**Episode 1: Enhanced Refinancing Efficiency from 1986 to 1993**

Price Bucket	Coupon (%)	Calibrated to 1986		Calibrated to 1993		Price Impact	Duration Bias (yrs)
		Price	Duration (yrs)	Price	Duration (yrs)		
Discount	6.78	96-00	5.05	95-17	4.87	0-15	0.18
Current	7.42	99-00	4.57	98-13	4.40	0-19	0.27
Cusp	7.85	101-00	4.23	100-10	3.93	0-22	0.30
Premium	8.52	104-00	3.51	103-02	2.90	0-30	0.61

**Episode 2: Enhanced Refinancing Efficiency from 1993 to 1998**

Price Bucket	Coupon (%)	Calibrated to 1993		Calibrated to 1998		Price Impact	Duration Bias (yrs)
		Price	Duration (yrs)	Price	Duration (yrs)		
Discount	6.89	96-00	4.86	95-28	4.80	0-04	0.06
Current	7.56	99-00	4.27	98-27	4.18	0-05	0.09
Cusp	8.0	101-00	3.73	100-25	3.51	0-07	0.22
Premium	8.69	104-00	2.77	103-19	2.50	0-13	0.27

\* All computations at 55 OAS. Yield curve and volatility structure as of 12/29/99.

largest for the premium coupon, with a bias of 0.61 during the first episode and a bias of 0.27 during the second.

We use this procedure to estimate the resulting impact on mortgage excess returns. The price, paydown, and duration effects are computed each month for each price bucket, assuming that refinancing efficiency increased uniformly between prepayment waves. The price effect is the negative valuation impact, at constant OAS, of the monthly improvement in refinancing efficiency. The paydown effect is calculated using the difference between market and production model prepayment forecasts and the price of the representative security. The impact of the duration bias is assumed to increase linearly between prepayment waves and depends on the interest rate movement in a given month. Duration bias affects excess returns negatively in months when rates rallied and positively in months when rates backed up.

The three effects are aggregated across the price buckets by market weight to compute the summary impact on index excess returns. As shown in Figure 5a, the price/paydown effect explains most of the discrepancy between OAS and average excess returns for the premium and cusp buckets. Duration bias also has a significant effect, explaining 18 bp of the underperformance of premiums. For the 30-year fixed rate MBS index, we attribute 32 bp of the 51 bp underperformance to the price/paydown effect and 15 bp to duration bias, leaving 4 bp unexplained.

What would have happened if interest rates had increased, rather than decreased, over the study period? The measured excess returns were lower by 15 bp because of incorrect durations and the decline in rates over the measurement period. If the market had backed up, the duration bias would have *increased* measured excess returns. We attempt to quantify this in Figure 5b. We altered the realized interest rate path from 1989-99 so that rates were 278 bp higher at the end of the period, rather than lower as actually happened. A small upward drift was added to rates every month to accomplish this.

Figure 5a. **Why Realized Excess Returns Were Lower Than OAS: An Approximate Attribution of the Slippage for 30-Year Mortgages, 1989-1999 . . .**

Source of Underperformance	Discount	Current	Cusp	Premium	30-Year Index
Price Return	6 bp/yr	8 bp/yr	12 bp/yr	19 bp/yr	16 bp/yr
Paydown Return	0	0	2	21	16
Duration Bias	8	16	16	18	15
<b>Total</b>	<b>14 bp/yr</b>	<b>24 bp/yr</b>	<b>30 bp/yr</b>	<b>58 bp/yr</b>	<b>47 bp/yr</b>
<b>Average Index Price</b>					<b>\$101-07</b>
OAS - Excess Return	15 bp/yr	40 bp/yr	43 bp/yr	73 bp/yr	51 bp/yr

Figure 5b. .... and What Would Have Happened If Rates Had Increased,

<b>Source of Underperformance</b>	<b>Discount</b>	<b>Current</b>	<b>Cusp</b>	<b>Premium</b>	<b>30-Year Index</b>
Price Return	6 bp/yr	8 bp/yr	12 bp/yr	19 bp/yr	7 bp/yr
Paydown Return	0	0	2	21	2
Duration Bias	-10	-19	-30	-20	-16
<b>Total</b>	<b>-4 bp/yr</b>	<b>-11 bp/yr</b>	<b>-16 bp/yr</b>	<b>20 bp/yr</b>	<b>-7 bp/yr</b>
<b>Average Index Price</b>					<b>\$ 97-10</b>

The changed rate path improved the index excess returns in two ways. First, the duration bias improved measured excess returns, as discussed earlier. Second, in this rate evolution, the index was more concentrated in discounts and par-coupon buckets—the average index price was \$97-10, instead of \$101-07. These buckets had smaller price and paydown effects than cusp and premium securities. In fact, Figure 5b indicates that had rates backed up instead of rallying, index excess returns would have exceeded OAS by 7 bp, on average.

---

### **SECTION III: HISTORICAL LINKAGES BETWEEN MORTGAGES AND OTHER FIXED INCOME SECTORS**

The mortgage market is tightly linked with other fixed income markets, as clearly demonstrated during the recent financial crisis of late 1998. In this section, we examine mortgage linkages with corporates and with Treasury rates. Our principal conclusions are:

1. Mortgage excess returns exhibit a strong correlation with corporate excess returns, ranging from 14% to 56%, depending on the duration/price bucket. Linkages between corporates and mortgages are strongest for discount mortgages and weakest for premium mortgages.
2. Despite the significant correlation over the 11-year period, across shorter time horizons, the correlation varied considerably, due to the shifting relative importance of common versus sector-specific risk factors. In general, the correlation increases when there are large positive or negative returns to either sector.
3. The systematic variation in mortgage-corporate correlation implies that traditional mean-variance type analysis is inappropriate for asset allocation decisions. We propose an alternative asset allocation framework that incorporates the current spread information, as well as the historical co-movement of asset returns.
4. Treasury rate movements and mortgage spread changes exhibit a strong negative correlation when the aggregate level of prepayment risk is high, as indicated by a high average price of the securities in the mortgage index. This causes mortgages to trade much shorter than model-implied durations when the index price is above \$102.

#### **LINKAGES BETWEEN MORTGAGES AND CORPORATES**

Mortgage and corporate excess returns are driven by both common and sector-specific factors. Large variations in common factors will cause mortgage and corporate excess returns to move in sympathy. For instance, if the expected inflation rate increases, the required nominal excess return for all sectors will also likely increase. Similarly, an increase in the premium for liquidity is likely to cheapen all spread sectors relative to Treasuries.

On the other hand, large variations in sector-specific factors will result in independent movements in mortgage and corporate returns. For example, corporate spreads move in response to the market's changing perception of economic conditions, with effects magnified for creditors with high financial and/or operating leverage. Meanwhile, mortgage excess returns vary with changes in the value of the embedded prepayment option, which in turn varies with changes in interest rate volatility and prepayment expectations. In addition, supply or demand shocks in a given sector, such as a large issuance of corporate debt or the entrance of a large new

buyer for mortgages, will cause unique variation in returns to that sector. The realized correlation between the two sectors will depend on the relative strength of the common versus sector-specific factors.

In Figure 6, we examine the correlation structure of monthly excess returns of mortgages and corporates over the 1989-1999 period. For all corporate classes, the mortgage-corporate correlation decreases with increases in the dollar price of mortgage securities. For instance, the correlation between intermediate A-rated corporate excess returns and mortgage excess returns declines from 0.42 for discount mortgages to 0.28 for premiums. This is easy to interpret. Spread duration is lower for premium mortgages than for discounts, which means that systematic spread movements explain a smaller fraction of the variation of premium excess returns. At the same time, refinancing shocks are more significant for premium mortgages. Overall, excess returns for premiums are driven more by mortgage-specific factors than excess returns for discounts, accounting for the lower correlation with corporates.

## CHANGES IN MORTGAGE-CORPORATE LINKAGES OVER TIME

There is considerable time variation in the average correlation numbers reported in Figure 6. As an illustration, we examine the correlation between A-rated intermediate corporates and current coupon mortgages, computed over rolling 24-month windows (Figure 7). This correlation fell steadily through the 1990s and was close to zero for much of the 1996-1997 period. However, during the two recent credit shocks—the Asian crisis of late 1997 and the global contagion fears of late 1998—all spread sectors moved in sympathy, causing the inter-sector correlation to spike to 0.8. This indicates that the use of historical correlations in a mean-variance asset allocation framework can often be misleading, especially if correlation is high in periods of large negative excess returns.

Figure 6. **Correlation of Monthly Excess Returns of 30-Year Mortgages and Selected Corporate Sectors**, January 1989-December 1999

Sector	Mortgages				
	Index	Discount	Current	Cusp	Premium
Corporate Index	<b>0.51</b>	<b>0.56</b>	<b>0.60</b>	<b>0.56</b>	<b>0.39</b>
A-Short	<b>0.38</b>	0.49	0.49	0.40	0.22
A-Intermediate	<b>0.42</b>	0.52	0.52	0.46	0.28
BBB-Short	<b>0.30</b>	0.47	0.44	0.31	0.14
BBB-Intermediate	<b>0.33</b>	0.46	0.46	0.36	0.20

\* See Figure 2 in Section II for a description of the corporate and mortgage sectors.

Figure 7. **Time Variation in Correlation of Excess Returns of Mortgages and Corporates, January 1991-December 1999\***

\* Correlations estimated using monthly data over a 24-month window for 30-year par-coupon mortgages and noncallable A-rated securities in the Lehman Brothers Corporate Index with 5-10 years to maturity.

Finally, we examine mortgage excess returns conditional on large negative and positive excess returns to A-rated intermediate corporates (Figure 8). Mortgages and corporates tend to move together when corporate excess returns are either strongly positive or strongly negative. When corporate excess returns are in the bottom quartile of their historic distribution, the mortgage-corporate correlation is 56%. Similarly, when corporate excess returns are in the top quartile, the correlation is 39%. On the other hand, when corporate excess returns are in the second or third quartile, the correlation is only 3%. The high mortgage-corporate correlation during periods of large positive and negative corporate excess returns is driven by the relatively strong influence of common versus sector-specific factors during periods of financial crisis. Similar results are observed when correlations are calculated conditional on mortgage excess returns.

## **INTEGRATING HISTORICAL PERFORMANCE AND CURRENT SPREADS IN AN ASSET ALLOCATION FRAMEWORK**

The systematic variation in mortgage-corporate correlation implies that traditional mean-variance type analysis is inappropriate for asset allocation decisions.<sup>6</sup> We develop an alternative asset allocation framework based on the historical variability of returns and current spreads. Four asset classes are considered: the ABS, Agency, Corporate and Mortgage indices. We begin by noting that for a default-free, non-callable security, the current spread is a fair indication of the expected excess return over Treasuries. The spreads on credit sensitive corporate debt must be adjusted down to account for expected losses, as well as the price impact of net downgrades. For a callable security, the OAS is the expected return.

However, investment decisions cannot be based on expected returns alone; the distribution of returns about the mean is also important. This distribution of returns is a function of the terminal spread of the security; a widening causes realized returns to fall below expected returns. Since there are no liquid instruments to infer the terminal distribution of spreads, we have developed a methodology to simulate the return distribution. This methodology is based on the assumption that the variability of returns over the investment horizon will be similar to that observed in the past. In the subsections below, we illustrate this methodology based on spread information as of December 29, 1999.

### **Specifying Expected Excess Returns**

Agencies can be considered default free, and we set the expected return equal to the current spread. For mortgages, the current OAS on the index overstates expected returns and needs to be adjusted down. As discussed in greater detail in Section V, our current prepayment model does not incorporate the expected increase in future callability due to enhanced refinancing efficiency. As a result, it overstates OAS on 30-Year MBS by 6-15 bp, the bias being greater for premiums relative to discounts. Since the mortgage market is currently dominated by discount loans (the weighted average price of the mortgage index is currently \$96.40), we adjusted the OAS on the mortgage index down by 6 bp to 58 bp. Finally, expected returns on corporates were set equal to the OAS less adjustments for defaults and the mark-to-market impact of downgrades and upgrades. Given the current composition of the corporate index and historical default and rating transition probabilities, we predict the average slippage due to defaults and ratings changes of 5 bp/year and 35 bp/year, respectively. The final estimates used in the asset-allocation exercise are shown in Figure 10.

---

<sup>6</sup> Another blow against mean-variance optimization is the considerable evidence that financial asset returns are "fat-tailed," i.e., using "Z scores" underestimates the true likelihood of extreme negative or positive returns.

---

### Simulation of Future Return Distribution

We simulated the distribution of annual excess returns for each sector using the following methodology:

1. The 132-month history (January 1989 to December 1999) of excess returns was used to generate future returns. We randomly selected 12 monthly excess returns from the historical series for each asset class. Combining these 12 random draws gave us one annual excess return observation. This process was repeated several thousand times to simulate the annual return distribution.
2. The distribution of each asset class was subsequently shifted such that the mean of the distribution was equal to the current expected excess return.

Figure 9 shows the distribution of annual returns for the MBS index, with the negative excess return region representing underperformance relative to a Treasury benchmark. The probability of underperformance (29% in this case) is the area spanned by the probability bars in the underperformance region. This is a useful summary measure of risk for a portfolio manager and should be weighed against the expected return from the security.

Figure 10 summarizes this risk-return trade-off for the various asset classes considered. The ABS index offers the lowest probability of underperformance *and* the highest expected return. However, since we have a shorter history for this asset class (we have only 108 months of data for ABS), we have more reliable estimates for the other sectors. Agencies offer the lowest expected returns, but also have the lowest risk of underperformance. Portfolio managers can choose a combination of the four assets based on their risk tolerance. For instance, an asset manager who

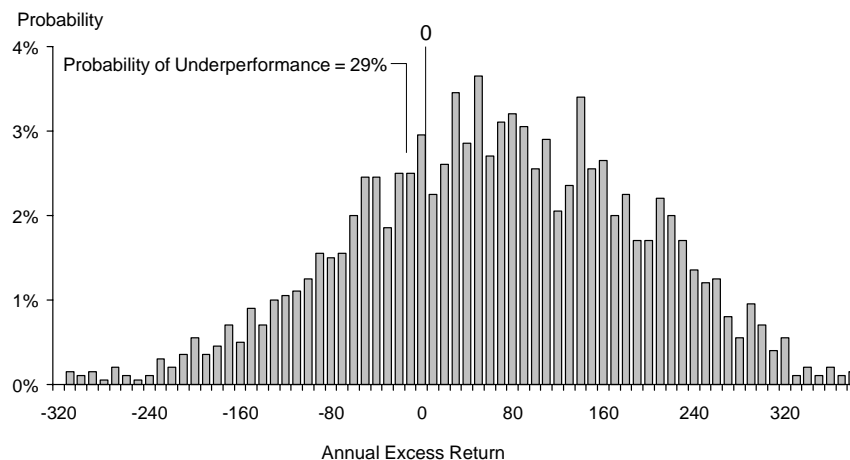

Figure 10. **Distribution of 1-Year Projected Excess Returns by Sector\***

Sector	Excess Return		Probability of Underperforming Treasuries
	Mean	S.D.	
ABS Index	76 bp	77 bp	0.12
Agency Index	34	39	0.13
Corporate Index	72	143	0.30
Mortgage Index	58	129	0.29

\* As of December 28, 1999

wants to keep the probability of underperformance below 13% should restrict attention to agencies. Those willing to live with the higher risk of underperformance should selectively add mortgages and corporates.

### Other Considerations

While the above analysis does provide a concrete risk-reward tradeoff, it does not account for the superior liquidity of mortgages relative to other fixed income sectors. This makes mortgages an ideal instrument for a tactical underweight or overweight to the spread sectors. This is especially important at the current moment, since the mortgage index is weighted in discounts, which have a higher correlation with other spread sectors than premiums (see Figure 6). Finally, given their high liquidity, mortgages provide an effective way to express views about both implied and realized volatility in the Treasury/swap market.

### LINKAGES BETWEEN INTEREST RATES AND MORTGAGE SPREADS

Mortgage excess returns have shown a strong positive correlation of 38% with interest rate changes over the past ten years. Part of this correlation is due to the duration bias identified in Section II. However, the more significant factor is mortgage spread directionality, i.e., mortgage spreads tend to widen in Treasury rallies and tighten in rate backups.

Why should par coupon OAS exhibit directionality in interest rates?<sup>7</sup> A possible explanation is that the premium for bearing prepayment uncertainty is a function of the level of rates. When Treasury rates rally, the average dollar price of outstanding MBS increases, and so does the aggregate prepayment risk borne by mortgage investors. If the existing level of prepayment risk is sufficiently high, every marginal increase in risk requires additional yield compensation. If the current

<sup>7</sup> This phenomenon is not attributable to the market prepayment model's being more callable than the estimated model used for valuation. While underestimating mortgage callability would make empirical durations shorter than model durations, it would not cause *par coupon* OAS to vary systematically with rates.

---

aggregate level of prepayment risk is relatively low, on the other hand, investors do not demand incremental yield to bear more prepayment risk. The average price of the Lehman Brothers Mortgage Index is a barometer of the aggregate level of prepayment risk in the economy; in particular, a high index price indicates a high level of prepayment risk.

### **Evidence of Directionality over the 1994-1999 Period**

To examine this relationship, we compare weekly changes in par coupon 30-year FNMA mortgage spreads with weekly changes in 10-year Treasury note yields. As shown in Figure 11a, there is a clear pattern between Treasury yield changes and changes in par coupon mortgage spreads when the index price is above \$102.

We report statistical analysis of the mortgage-Treasury relationship for different levels of the mortgage index in Figures 11b and 11c. When the index is above \$102, mortgage spreads are more than twice as likely to widen than tighten in a Treasury rally, and the two series have a large negative correlation of  $-0.51$ . Linear regression analysis shows that a 10 bp rally in the 10-year yield results in a 2 bp widening in par coupon OAS in this environment. When the index is trading in the \$98-\$102 price range, however, there is no evidence of a relationship between Treasury yields and mortgage spreads. There is weak support for a positive relation between mortgage spread changes and Treasury yield changes when the index is at a discount. However, the sign tests are inconclusive for this price range.

### **Implications of Mortgage Spread Directionality**

The directionality of mortgage spreads when the index price is high has several implications for portfolio managers. First, mortgage spreads and excess returns will be more volatile when the index is at a premium because of the systematic variation of OAS with Treasury rates in our sample. Over the 1994-1999 study period, monthly index excess returns were 40% more volatile when the index was trading above \$102. Second, empirical durations will be shorter than model durations when the index price is high, since spread changes will tend to dampen mortgage price movements. When the index price is above \$102, spread directionality causes par coupon mortgages to trade at approximately 80% of their model-implied durations.

## **SECTION IV: EMPIRICAL TESTING FOR RISK FACTORS IN MORTGAGES**

The preceding analysis considers the past behavior of mortgage excess returns and their relationship with other fixed income sectors. It suggests that spread changes in competing fixed income products, as well as movements in Treasury rates, have a significant effect on mortgage excess returns. From our theoretical understanding of MBS as a short position in a prepayment option, we know that volatility and prepayment surprises are important determinants of mortgage performance. In this section, we examine the collective impact of these variables on mortgage excess returns.

1. Five key drivers of mortgage excess returns—realized volatility, implied volatility, aggregate prepayment surprises, common movements in fixed income spread sectors, and OAS directionality—together explain between 40% and 59% of the variation in mortgage excess returns.
2. While all of these risk factors were significant, the most important risk factors were realized and implied volatility, which combined to explain 18%-28% of the variation in excess returns, and credit spread movements, which explained 8%-39% of variation in excess returns.

### **THE FIVE KEY RISK FACTORS IN MORTGAGE EXCESS RETURNS**

In seeking a simple empirical model, we propose five key drivers of mortgage excess returns. These five factors are suggested by our general understanding of the behavior of mortgage prices and are supported by empirical evidence. Proxies for these variables are chosen both for their strong linkages with the mortgage market and for the quality of historical data. The five factors and their proxies are:

1. *Convexity* (Realized interest rate volatility): Squared changes in the off-the-run 10-year par Treasury yield are used to capture the impact of convexity.
2. *Vega* (Changes in the term structure of implied volatility): This variable is proxied using changes in the Black volatility of 5-year maturity options on the 10-year swap rate.
3. *Prepayment Surprises*: The surprise in the MBA refinance index (see discussion below) is used to measure the impact of unanticipated prepayments on mortgage returns.
4. *Spread changes*: The impact of changes in the spread of competing fixed income securities is captured through movements in 5-year swap spreads.
5. *Directionality*: This variable refers to the mortgage-treasury correlation when there is a high aggregate level of prepayment risk. It is proxied using changes in the off-the-run 10-year par Treasury yield when the index price is above \$102.

---

### A Simple Proxy for Market-Wide Prepayment Surprises

Our variable for prepayment surprises requires some discussion. It would be naive to expect prepayment model forecast errors to be a surprise to the market. Changes in proprietary prepayment models typically lag updates to market prepayment expectations. Instead, we propose a proxy based on unanticipated changes in the MBA Refinance Application Index, a commonly tracked measure of refinancing activity. While this does not identify security-specific surprises, it does capture prepayment surprises in the aggregate. The first step in the computation is to forecast the MBA Refinance Index as a function of the aggregate refinancing incentive. The market-weighted sum of the refinancing incentive of all securities in the Lehman Brothers Mortgage Index is used as a proxy for the aggregate refinancing incentive. As shown in Figure 12, the MBA index closely tracks the aggregate refinancing incentive over the period of study, with significant deviations appearing only in 1998.

We estimate the sensitivity of the MBA index to changes in aggregate refinancing incentive using a linear regression over a 36-month rolling window. This estimated sensitivity is used to generate a month-ahead estimate of the change in the level of the MBA index conditional on the next month's change in the aggregate refinancing incentive. The surprise in the MBA index, measured as the difference between the actual and predicted MBA index, is used as a proxy for market-wide revisions in prepayment views (Figure 13). The variable clearly identifies the sharp and unexpected spikes in the Refinance Index in January and October, 1998.

---

Figure 12. **MBA Refinance Index versus Aggregate Refinancing Incentive**, January 1994-December 1999

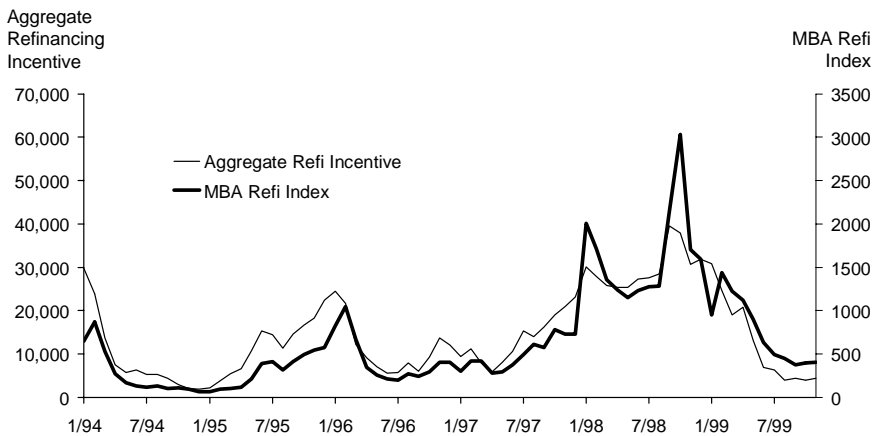

Figure 13. **Innovation (Actual minus Projected) in the MBA Refinance Index, January 1994-December 1999**

### Model Estimates of Risk Sensitivities

A linear multiple regression is a robust way to quantify the collective impact of the various drivers of mortgage excess returns. The coefficient estimates from the regression can be considered the empirical risk sensitivity of excess returns to the risk factors and should be comparable to the theoretical estimates from our valuation models. Figure 14 lists selected model risk sensitivities for benchmark unseasoned mortgages as of November 30, 1999.

Convexity is the analogue of the gamma of an option. Extending the options analogy, at-the-money options—the cusp coupon securities—have the highest negative convexity. Vega, the sensitivity of MBS prices to changes in the implied volatility of Treasury rates, declines as we go up in coupon. To interpret this, it helps to think of an MBS as a long position in a Treasury and a short position in a portfolio of several call options. In this framework, a discount MBS is short out-of-the-money call options, while a premium MBS is short in-the-money call options. Since

Figure 14. **Theoretical Risk Measures for 30-Year FNMA Pass-throughs, November 30, 1999**

Coupon	Price	Convexity	Vega (32nds)	Prepayment		ZV Spread	OAS
				Duration (32nds)*	Spread Duration		
7.0	97-21	-0.9	-8	-2	4.8	96	50
7.5	99-23	-1.5	-8	-3	4.5	112	54
8.0	101-14	-2.2	-8	-4	4.1	132	60
8.5	103-04	-2.2	-6	-5	3.7	144	70

\*For a 10 bp shift in the refinancing elbow.

---

implied volatility has a larger impact on out-of-the-money relative to in-the-money options, discounts generally have a higher vega relative to premiums.

Prepayment duration, which measures the change in price due to a 10 bp decline in the refinancing threshold (elbow), increases with MBS price. Again using the option analogy, a decline in the refinancing threshold implies lowering the strike rate for all the embedded call options. The impact of this decline is larger for the in-the-money call options embedded in premiums rather than the out-of-the-money options embedded in discounts. Finally, spread duration, which measures the percent change in price due to a 100 bp widening in Treasury spread, is declining in price; a straightforward consequence of the longer average life of discounts relative to premiums.

### **TESTING THE FIVE-FACTOR MODEL**

We test the five-factor representation of excess returns over the July 1994 to December 1999 time period.<sup>8</sup> The model is tested using monthly excess returns of four price-sorted (Discount, Current, Cusp, and Premium) portfolios of TBA 30-year conventional mortgages. To determine the explanatory power of the five factors, alone and in combination with other factors, we regress excess returns on an intercept and:

- 1) Each individual risk factor;
- 2) The two volatility factors, vega and convexity; and
- 3) All five risk factors together.

In Figure 15, we display the coefficient estimates, or the empirical risk sensitivities, from the multiple regression, which can be compared to the model determined sensitivities reported in Figure 14. The size of the coefficient is not an adequate measure, however, of the significance of the factor in determining mortgage returns; the variability of the factor is also an important consideration. For instance, if the Federal Government explicitly repudiates its implicit guarantee of the GSEs, it would have a significant impact on the mortgage market. However, if the likelihood of this event is not expected to change in the foreseeable future, it would not be a significant driver of mortgage excess returns. In Figure 16, we have computed the partial contribution of each of the risk factors to the total excess return variability. We discuss these results below.

### **Empirical Estimates of Risk Sensitivities**

Empirical convexities, ranging from -1.2 to -2.7, are roughly comparable to theoretical risk measures, while empirical vegas, ranging from -2.5 to -4.7/32nds, are less negative than theoretical vegas. At first blush, this difference suggests that mortgage prices are less sensitive to changes in implied volatility than our valuation

<sup>8</sup> The sample period was limited by the availability of price data on longer-maturity swaptions. TBA FNMA's were chosen for their high-quality return data, which results from their higher liquidity.

Figure 15. **Empirical Risk Measures for 30-Year Agency Fixed-Rate Mortgages, July 1994-December 1999**

		Convexity	Vega*	Prepayment Surprise	Spread Duration	Directionality	ZV	% of Variation Explained

	t-stat	(-2.2)	(-2.1)	(-3.0)	(-2.9)	(-1.9)	(2.1)	

\*In 32nds.

model indicates. However, we suspect that some econometric issues are biasing our coefficient estimates. For instance, if mortgage prices do not adjust instantaneously to changes in implied volatility, it would bias the coefficient estimates towards zero. Swap spreads are significant for all price buckets, and the coefficient estimates are comparable to theoretical measures. Our estimate for the surprise in the MBA refinancing index is significant for all non-discount price buckets and is most pronounced for current and cusp coupon mortgages. This pattern is not consistent with Figure 14, where premiums have the highest prepayment sensitivity, and underscores the inadequacy of our proxy as a measure for prepayment surprises. Finally, the directionality of mortgage spreads is significant for current coupon mortgages, which trade 0.8 years shorter than their theoretical duration. For other buckets, the effect of directionality is limited. The unexplained variation in excess returns ranges from 40%-60%, which can be attributed largely to prepayment related factors that are not easily captured through any measured variable.

#### **How Well Does the Model Explain Variation in Excess Returns?**

The five-factor model does a good job of explaining variation in excess returns, as measured by the R-squared statistic from the regressions (Figure 16). The variation in the five risk factors explains 52%-59% of the variation in excess returns of non-premium mortgages and 40% of the variations in excess returns of premiums. Realized volatility is the most important risk factor, explaining 5%-14% of the variation in excess returns. The two volatility risk factors, realized and implied volatility, together explain 18%-28% of the variation in excess returns of 30-year mortgage returns. Credit spreads have high explanatory power for lower-priced mortgages, reaching a maximum of 39% for discounts. The measured prepayment risk factor explains 7%-13% of the variation in the prepayment-sensitive current, cusp, and premium mortgages. Finally, spread directionality appears to be an important factor only for current coupon mortgages.

Figure 16. **Contribution of Risk Factors to Observed Mortgage Excess Returns, July 1994-December 1999**

## SECTION V: OUTLOOK

The preceding analysis has shed light on the historical behavior of mortgage returns: their past performance, their interrelationships with other fixed income sectors, and their key drivers. This understanding of past return behavior provides a basis for insights into future mortgage performance. Looking forward, we expect the following:

1. Refinancing costs will decline significantly over the next 3-5 years due to increased automation in mortgage underwriting, access to refinancing over the Internet, and technological improvements in the title search process;
2. Our production prepayment model, which does not build in this increased efficiency, currently overstates durations by 0.1-0.3 years and OAS by 6-15 bp. Once the full improvements in efficiency are realized, par-coupon duration will be 0.4 years lower, and option cost will be 15 bp higher; and
3. In setting Treasury hedge ratios, investors should account for spread directionality when the mortgage index is at a premium.

### REFINANCING EFFICIENCY WILL CONTINUE TO IMPROVE

Increasing refinancing efficiency has had a significant impact on past excess return performance. Our current prepayment model does not build in improvements in refinancing technology, and, therefore, the reported OAS overstate expected excess returns. To gauge the impact of continuing technological innovation, we have attempted a preliminary assessment of the potential for future cost savings and its impact on MBS valuation.

Figure 17 reports the cost breakdown for refinancing a \$130,000 loan in a typical state.<sup>9</sup> Brokerage represents the cost of soliciting customers. The underwriting/processing item includes all the costs incurred from the receipt of application to loan closing, including appraisal and closing.

Each of these cost items is under siege due to industry consolidation, automation, and Internet usage. With increasing Internet usage, we expect brokerage costs to decline from \$395 to \$200 for a refinancing transaction (originators currently pay \$30-\$50 to Internet portals for loan referrals). Industry sources indicate that processing costs will decline by 30%, due to automation, over the next 3-4 years. Furthermore, many mortgage companies are now using sophisticated statistical techniques to get reasonable estimates of home value without a detailed physical examination of the home, sharply reducing third party costs. Based on this analysis,<sup>10</sup> we estimate that the fixed costs of refinancing a loan could decline by

<sup>9</sup> Refinancing costs vary substantially across states due to differences in title insurance, legal requirements, and recording taxes.

<sup>10</sup> For more details about the future of refinancing costs, see the prepayment section in the Lehman Brothers publication *The MBS/ABS Markets in Y2K: Opportunities and Challenges*.

Figure 17. **Mortgage Origination—Current versus Projected Cost Structure for a \$130,000 Loan**

	<b>Current (2000)</b>	<b>Forecast (2004)</b>	<b>Savings</b>
<b>Fixed Costs</b>			
• Brokerage	\$ 395	\$ 200	
• Underwriting/ Loan Processing	475	330	
• Appraisal and Credit Check	470	200	
• Legal	400	400	
• Govt. Fees	<u>170</u>	<u>170</u>	
<b>Total Fixed Costs</b>	<b>1910</b>	<b>1300</b>	<b>\$650 (32%)</b>
<b>Variable Costs</b>			
• Title Insurance	0.6%	0.4%	
• Govt. Taxes	<u>0.3%</u>	<u>0.3%</u>	
<b>Total Variable Costs</b>	<b>0.9%</b>	<b>0.7%</b>	<b>0.2%</b>

\* Source - E-Loan (online mortgage broker) and Lehman Brothers Research.

32%. In our view, this is an optimistic scenario from the perspective of mortgage investors, and the potential exists for a significantly larger reduction in fixed costs associated with refinancing. Finally, the increasing computerization of court records will reduce the cost of the title search and insurance. Our analysis suggests that a 30% reduction in title insurance costs is likely over the next 3-5 years, implying a 20 bp decline in the variable costs of refinancing.

While the implication of a decline in variable costs is a straightforward shift in the refinancing threshold, the impact of decreasing fixed costs is more complex. To simplify the analysis, we note that, from a callability perspective, a decline in fixed costs is equivalent to an increase in loan size, i.e., the refinancing threshold of a borrower with a given loan balance and level of fixed costs is identical to that of another borrower who has a loan twice as large and incurs twice the fixed costs. Consequently, the 32% projected decline in fixed costs is equivalent to an increase in the loan balance of 47% (1/0.68). Since the average jumbo loan size is about double that of agencies, the lower fixed costs should move agency mortgages about halfway along the current callability gradient from agencies to jumbos. This analysis implies a further 25 bp inward shift in the refinancing threshold (in addition to the 20 bp shift due to variable cost savings) and a 15% increase in the slope of the refinancing function.

### **Valuation Impact of Expected Technological Innovation**

We assumed that the reductions in refinancing costs would be achieved in four years. We simulated a gradual and uniform increase in callability over the next four years and show the current valuation impact on representative securities in Figure 18a. Naturally, the valuation impact will be greater once the efficiencies

are fully realized, i.e., in January 2004. This is reported in Figure 18b, where we have computed OAS and durations with the full increase in callability at today's prices, yield curve, and volatility environment.

Not surprisingly, the largest impact is on premiums. The current OAS impact for TBAs varies from 6 bp for discounts to 15 bp for premiums (Figure 18a). After the full increase in callability (Figure 18a), an unchanged prepayment model would understate OAS by 9-24 bp and durations by 0.1-0.8 years. Naturally, we expect the market to progressively price the increasing callability. Figure 18b indicates how much the value of an MBS will erode over time due to greater callability, even if the rate and volatility environment remains unchanged.

We emphasize that this analysis understates the true impact of the continuing transformation of the mortgage banking industry. For example, we do not forecast any change in refinancing sensitivity after four years. The industry will continue to

Figure 18a. **Current Impact of Projected Improvements in Refinancing Efficiency on Valuation of 30-Year Conventional TBA Mortgages;** December 29, 1999

Coupon	Price	No Improvement		Projected Improvement*		Change	
		OAS	OAD	OAS	OAD	OAS	OAD

9.0	104-19	77	2.6	53	1.9	24	0.7

\* Due to an increase in refinancing sensitivity (the refinancing threshold declines by 45 bp and the slope increases by 15%).

evolve, and costs are likely to be squeezed relentlessly. However, this limited analysis does highlight the relative sensitivities of different securities to this source of risk.

### How Should Mortgages Be Hedged?

The analysis in this paper should provide some guidance on appropriate hedging techniques for mortgages. The empirical model in Section IV suggests that five factors drive most of the variation in excess returns. To be sure, the exposure to prepayment surprises is difficult to hedge, and investors should get compensated for prepayment exposure. However, the other four factors are readily hedgeable. Most investors already dynamically manage the duration of their mortgage positions. However, the evidence shows that mortgages have a significant exposure to vega risk, which can be hedged using derivatives such as swaptions. The significant role of swap spread changes suggests that swaps are a better hedge for mortgages than Treasuries. The existence of spread directionality implies that managers must adjust their hedge ratios when the mortgage market trades at a premium, i.e., the mortgage index is priced above \$102.

The adjustment of model hedge ratios is not a straightforward task; most mortgage investors have struggled to find the appropriate adjustment, particularly over the past year. Empirical durations have often deviated from model durations, and this relationship has varied considerably over time. The analysis in this paper, coupled with our expectations about future refinancing efficiency gains, suggests a framework for hedging mortgages. Therefore, as a first step to improve hedging precision, investors should use forward-looking prepayment models, as detailed in Figures 17 and 18. A further refinement would take into account the relationship between spread directionality and the level of the index, as discussed in Section III.

A preliminary attempt to measure the combined impact of refinancing efficiency and spread directionality is shown in Figure 19. Based on the preceding analysis, the duration of current coupon mortgages (7.5s) should be adjusted downward from 4.2 to 3.4 if the index price is above \$102, due to spread directionality. Incorporating future refinancing efficiencies will reduce this duration by an incremental 0.2 years, resulting in a combined impact of 1.0 years. Similarly, the duration of 8.5% mortgages should be adjusted downward by as much as 0.8 years.

Figure 19. **Combined Impact of Refinancing Efficiency and Spread Directionality on Durations of 30-Year Conventional TBA Mortgages;** December 29, 1999

Coupon	Index Price	Improvement in Refinancing	
		None	Projected
7.5%	< \$102	4.2	4.0
7.5	> \$102	3.4	3.2
8.5%	< \$102	2.7	2.4
8.5	> \$102	2.1	1.8

---

### **Concluding Comment**

We recognize that this is only a first step in the empirical analysis of mortgage excess returns and the implications for hedging mortgages, as well as fixed income asset allocation. Much work remains to be done in refining the analysis, as well as making concrete recommendations for portfolio managers. We look forward to working jointly with our clients to continue to build a better foundation for understanding mortgage returns.

LEHMAN BROTHERS
